INTRODUCTION

Belgian Blue Calves (BBC) are double-muscled beef cattle, representing a valuable investment to the farmer. Little is known about volume status assessment in bovine medicine. In human and companion animal medicine, ultrasonographic assessment of the inferior/caudal vena cava diameter (CVCc) is used as an inexpensive, rapid and noninvasive marker to evaluate intravascular volume status. The objective of this study was to perform a pilot study on the feasibility to obtain ultrasonographical measurements of the caudal vena cava diameter (CVCc) and area (CVCa), aortic diameter (AoD) and area (AoA) via the longitudinal right paralumbar (PV) and subxiphoid (SX) view in awake healthy calves, as previously described in dogs. Secondly, we wanted to assess whether those values change with the calf growth.

METHODS: We performed a single observer prospective observational study in standing healthy calves at t1 (calves 1 month old) and at t2 (2,5month later) using a microconvex curvilinear (5-7MHz) probe. BBCs were deemed healthy based on history and clinical evaluation excluding diseases potentially influencing intravascular status.

RESULTS: 17 BBC were enrolled, 10 male and 7 female, with a median age of 36 days (range 33-41 days) at t1, 114 days (range 100-136 days) at t2. The median weight was 70kg (range 51 to 90 kilos) at t1, and 134kg (range 103 to 170) at t2. Measurements were obtained in all 17 BBC at the PV view in t1 and t2. The subxiphoid view was performed in 14 calves in t1 and interpretable ultrasound images were obtained only in one. SX view appeared too difficult to perform, it was no longer attempted in heavier calves in t2. Statistical analysis of paired data (t-test paired and Wilcoxon) for each calf showed significant differences between CVC and Ao diameter and area in t1 and t2, excepted for aorta area in transversal PV view (Fig.6). CVC and Ao ratio showed also significant differences (Fig 7a and b).

CONCLUSION

CVC and Ao assessment were easily performed at the PV view, yet only rarely achieved at the SX view in awake healthy calves. This pilot study also showed that caudal vena cava and aortic size (mean or median) seem to increase when calves grow, except for aorta area in transversal paralumbar view. Against expectations, both caudal vena cava and aorta ratios seem to increase with growth.
